Homoepitaxial growth is unstable towards the formation of pyramidal mounds when interlayer transport is reduced due to activation barriers to hopping at step edges. Simulations of a lattice model and a continuum equation show that a small amount of desorption dramatically speeds up the coarsening of the mound array, leading to coarsening exponents between 1/3 and 1/2. The underlying mechanism is the faster growth of larger mounds due to their lower evaporation rate.

Growth of perfectly smooth epitaxial layers, e.g., for the fabrication of two-dimensional electron-gas heterostructures, requires suppressing growth instabilities that lead to surface roughening. However, one can also try to harness the instabilities and make them produce regular arrays of tiny objects on the crystalline substrate, such as quantum wires and quantum dots. Much attention has been paid to nanostructures created during heteroepitaxial growth. It seems tempting to use also other types of instabilities associated with homoepitaxy.

The most prominent of these kinetic instabilities is the creation of pyramidal features on the surface as a result of additional activation barriers to hopping at step edges reducing interlayer transport [1,2]. Theoretical [3–8] and experimental [8,9] research has shown that the array of pyramidal mounds coarsens in time with the average mound size  $\xi(t)$  increasing according to a power law,  $\xi \propto t^{1/z}$ . Under the standard assumption of negligible desorption, which implies volume conservation for the growing film [1], the exponent 1/z was demonstrated to have an upper bound of 1/4 [10,11]. Here we show, using kinetic Monte Carlo (KMC) simulations and numerical integration of a continuum equation of motion, that even a minute amount of desorption drastically changes this situation with 1/z increasing towards 1/2. Detailed investigation of growth kinetics reveals that the reason is a dependence of the evaporation rate on the mound size, leading to faster growth of big mounds at the expense of small ones.

Monte-Carlo simulations. To study epitaxial growth with desorption, we used a solid-on-solid KMC model in which the crystal is assumed to have a simple cubic structure with neither bulk vacancies nor overhangs allowed. The basic processes included in our model are the deposition of atoms onto the surface at a rate F, their surface diffusion, and evaporation from the surface. The diffusion of surface adatoms is modeled as a nearest-neighbor hopping process at the rate  $k_D = k_0 \exp(-E_D/k_BT)$ , where  $E_D$  is the hopping barrier, T is the substrate temperature, and  $k_B$  is Boltzmann's constant. The prefactor  $k_0$  is the attempt frequency of a surface adatom

and is assigned the value  $10^{13}$  s<sup>-1</sup>. The barrier to hopping is given by  $E_D = E_S + nE_N + (n_i - n_f)\Theta(n_i - n_f)E_B$  where  $E_S$ ,  $E_N$ , and  $E_B$  are model parameters, n is the number of in-plane nearest neighbors before the hop,  $n_i$  and  $n_f$  are the number of next-nearest neighbors in the planes beneath and above the hopping atom before  $(n_i)$  and after  $(n_f)$  a hop, and  $\Theta(x)=1$  if x>0, and 0 otherwise (cf. Ref. [4] for a more detailed description of the model). The evaporation of a surface adatom occurs at the rate  $k_{\rm ev} = k_0 \exp(-E_{\rm ev}/k_B T)$ , where  $E_{\rm ev} = E_0 + nE_N$  with  $E_0$  being the energy for evaporation of a free surface adatom.

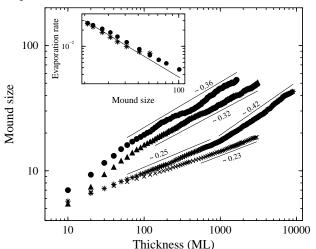

FIG. 1. Lateral mound size  $\xi(t)$  evolution for different model parameters and growth conditions obtained in KMC simulations. The model parameters used were  $E_0$ =1.9 eV at T=750 K,  $R_i$ =0 (stars) and  $R_i$ =3 (circles),  $E_0$ =2.0 eV at T=750 K,  $R_i$ =3 (crosses), and  $E_0$ =1.75 eV at T=670 K,  $R_i$ =3 (triangles). The slopes indicated are results of least-squares fitting. The error bars of the exponents (estimated from run-to-run variations) are of the order of 0.01. Inset: Size-dependent contribution to the evaporation rate of a single mound determined on lattices of size 21, 23, 27, 31, 35, 41, 51, 61, 71, 81, and 101 with periodic boundary conditions. Data show average over 25 runs, in each of which about 1000 ML were deposited. The full line has the form  $\Delta v = A/\xi^{1.5}$ , and is consistent with coarsening exponents for the same model parameters.

The simulations were carried out on square  $300\times300$  to  $600\times600$  lattices with periodic boundary conditions. The basic set of model parameters and growth conditions used was:  $E_S=1.54$  eV,  $E_N=0.23$  eV,  $E_B=0.175$  eV, and F=1/6 monolayer (ML)/s (set I of Ref. [4]). Under these conditions the equilibrium evaporation flux  $F_{\rm eq}=k_0\exp[-(E_0+2E_N)/k_BT)]\approx(10^{-3}-10^{-2})\times F$ , and the actual desorption rate is a few times larger. The robustness of the observed behavior was tested by using different temperatures and evaporation barriers  $E_0$ , and by including the "incorporation radius" effect whereby the incoming atom is placed at the site with the highest number of lateral nearest neighbors within a square area of size  $R_i$  centered on the site of incidence [4].

Simulation results are shown in Fig. 1 [12]. As the desorption rate increases, coarsening becomes faster and the coarsening exponent 1/z becomes much bigger than 0.19-0.26, the range of values observed in previous simulation work using the same model without desorption [4]. Even a rather small amount of desorption [13] thus drastically affects the coarsening exponent regardless of the details of the simulation model (such as the model parameters and the incorporation radius). In the regions of fits shown in Fig. 1 the mound slope stays approximately constant, indicating that the asymptotic regime has been reached. An interesting feature of Fig. 1 is the crossover observed for the case  $R_i = 0$  after approx. 1000 ML were deposited. We discuss the underlying change in the mechanism of coarsening below.

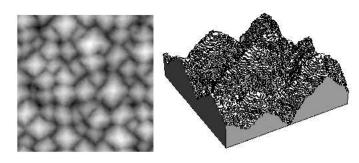

FIG. 2. Surface morphology in KMC simulations after approx. 2000 ML have been deposited. The displayed part of the lattice is  $300\times300$  (plane view, left) and  $100\times100$  (perspective plot, right).

Fig. 2 shows plane and perspective views of the surface morphology after approx. 2000 ML have been deposited. Pyramidal mounds are separated by narrow, deep troughs. The surface profile is clearly asymmetric with flat, rounded mound tops and sharp, deep valleys. For the case of  $R_i = 3$ , mounds are much shallower and bigger, having also more regular structure. In both cases, however, very fast coarsening is observed.

Continuum equations. Further confirmation of the dramatic effect of evaporation comes from continuum theory, where the surface is modeled by a smooth, space and time-dependent height function  $H(\mathbf{x},t)$ . Our start-

ing point is the standard continuum equation for unstable epitaxy [7,10], to which the leading order effect of desorption is added in terms of a slope-dependent growth rate  $V(|\nabla H|)$ :

$$\frac{\partial H}{\partial t} = -K\Delta^2 H - \nabla \cdot [f(|\nabla H|^2)\nabla H] + V(|\nabla H|). \quad (1)$$

In the absence of desorption  $V(u) \equiv F$ , the external flux. For a vicinal surface with step spacing  $\ell$  (tilt  $u = a/\ell$ , with lattice constant a), the growth rate according to BCF theory reads [14]  $V_{\rm BCF}(\ell) = (Fx_s/\ell) \tanh(\ell/x_s)$  where  $x_s = 2\sqrt{D\tau}$  is the desorption length, depending on the diffusion coefficient D and the desorption rate  $1/\tau$  from a flat surface.

To use the BCF-expression also for near singular surfaces [15], we introduce an effective, tilt-dependent step spacing  $\ell_{\rm eff}$ , which equals  $\ell$  in the step flow regime,  $u\gg a/\ell_D$ , and reduces to the terrace size or island distance [16]  $\ell_D$  for small u. Desorption is considered a small, perturbative effect in the sense that

$$\alpha \equiv \ell_D / x_s \ll 1, \tag{2}$$

which means that it is much more likely for an atom to be captured at a step than to desorb. Under this condition the terrace size  $\ell_D$  should not be influenced by desorption. A plausible formula for  $\ell_{\rm eff}$  is  $\ell_{\rm eff}(u) = \ell_D [1 + u^2 (\ell_D/a)^2]^{-1/2}$ , and the growth rate is then  $V(u) = V_{\rm BCF}(\ell_{\rm eff}(u))$ . Because of (2),  $\ell_{\rm eff}(u) \le \ell_D \ll x_s$  for all slopes, and therefore we can expand  $V_{\rm BCF}$  to obtain

$$V(u) \approx F[1 - (\alpha^2/3)(1 + u^2(\ell_D/a)^2)^{-1}].$$
 (3)

The growth rate varies between  $V(0) = F[1 - (1/3)\alpha^2]$  for the singular surface and F for  $u \gg a/\ell_D$ .

In the second term on the right hand side of Eq. (1) we set  $f(u^2) = f_0[1 - (u/m_0)^2]$ , which leads to a stable selected slope  $m_0$  [3] as is observed in our lattice simulations [17]. We subtract the deposited film thickness,  $H \to H - Ft$  and rescale time, lateral space, and height variables to arrive at the dimensionless form [10]

$$\frac{\partial h}{\partial t} = -\Delta^2 h - \nabla \cdot \left[ \left( 1 - (\nabla h)^2 \right) \nabla h \right] - \frac{\alpha^2 / 3}{1 + (\nabla h)^2}. \quad (4)$$

The one-dimensional version of (4) with an evaporation rate  $\sim (\nabla h)^2$  was considered in a different context by Emmott and Bray [18].

We integrated Eq. (4) numerically (for the method and system sizes see [19]) and found similar behavior as in the lattice model. After an initial fast increase of the lateral mound size  $\xi$ , the pattern coarsens as in the case without evaporation,  $\xi \sim w \sim t^{1/4}$  [10] (w is the mean square width of the surface,  $w^2 = \langle \tilde{h}^2 \rangle$  where  $\tilde{h} = h - \langle h \rangle$  denotes the height profile relative to its mean). This behavior is transient and eventually crosses over to a fast

asymptotic increase of the mound size and the surface width as  $\xi \sim w \sim t^{1/2}$ . The mound size  $\xi(t)$  is shown in Figure 3 for values of  $\alpha^2/3$  ranging from  $10^{-1/2}$  to  $10^{-3/2}$ , decreased by a factor  $10^{-1/8}$  between succeeding curves. The transient  $t^{1/4}$ -regime is absent for the strongest evaporation  $(\alpha^2/3=10^{-1/2})$  and becomes more pronounced as  $\alpha$  is decreased. A similar crossover is observed in the KMC simulations with  $R_i=0$  (stars in Fig. 1).

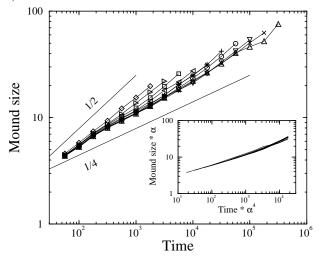

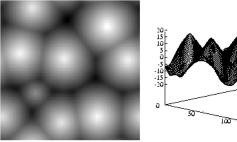

FIG. 3. Lateral mound size  $\xi(t)$  for nine different evaporation strengths  $\alpha^2/3=10^{-1/2},\ 10^{-5/8},\ 10^{-3/4},\ \dots,\ 10^{-3/2}$  obtained by numerical integration of the continuum equation. The transient regime  $\xi\sim t^{1/4}$  persists until evaporation dominates the surface driven coarsening at  $t_\alpha\sim\alpha^{-4}$ , the crossover time to asymptotic fast coarsening  $\xi\sim t^{1/2}$ . Scaling plot in the inset shows time  $t\times\alpha^4$  and length  $\xi\times\alpha$ .

The evaporation term in Eq. (4) breaks the up-down symmetry  $(h \leftrightarrow -h)$  [20]. When it is dominant (in the fast coarsening regime at late times) the surface morphology is asymmetric. The profile shown in Figure 4 consists of conical mounds separated by well defined, narrow valleys. Notice that there are no "negative mounds". The greyscale plot shows the cellular arrangement of the cones. The observed features are very similar to results of simulations in Fig. 2.

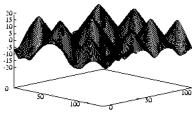

FIG. 4. Surface profile from continuum equation (evaporation  $\alpha^2/3=10^{-1/2}$ ) at late times when  $\xi\sim t^{1/2}$ . Conical mounds (right) form a cellular structure visible in the greyscale representation (left).

The origin of fast coarsening. Allowing for evaporation fundamentally changes the nature of the growth instability, because it introduces a coupling between the local growth rate and the surface morphology. In particular, one expects generically a dependence of the average growth rate of a mound on its size, while for conserved growth only the *fluctuations* in the growth rate are size dependent [21]. To see how this can affect the coarsening law, assume that the growth velocity of a mound depends on its size  $\xi$  as

$$v(\xi) = v_0 - \Delta v(\xi)$$
 where  $\Delta v(\xi) \sim \xi^{-\nu}$  (5)

with a positive prefactor, so that large mounds grow faster. If  $\xi$  is the only macroscopic length in the system, the size differences between mounds are also of the order of  $\xi$ . The time scale on which a small mound is eliminated by its larger neighbors is then given by  $t_{\xi} \sim w/\Delta v(\xi)$ , since the surface width w equals the typical height of mounds. Using that the mounds have a constant slope,  $w \sim \xi$ , it follows that  $\xi \sim t^{1/(1+\nu)}$  or  $z=1+\nu$ . Provided  $\nu < 3$  this violates the bound  $z \geq 4$  obtained in the conserved case [10].

A well-known mechanism for a size-dependent growth rate is the Gibbs-Thomson-effect: For spherical droplets in equilibrium the evaporation rate is proportional to the curvature  $\sim 1/\xi$ , hence within the Wilson-Frenkelapproximation [22] the growth rate is of the form (5) with  $\nu = 1$ . The mounds in our lattice simulations are more conical in shape, with rather straight sides and rounded regions of lateral extent  $\approx \ell_D$  at the tips. Assuming that desorption occurs preferentially from the tip regions, the evaporation rate of a mound of size  $\xi$  has a contribution proportional to the ratio of the tip area  $\sim \ell_D^2$  to the mound area  $\sim \xi^2$ , leading to  $\nu = 2$  and 1/z = 1/3. For a more quantitative estimate,  $\Delta v(\xi)$  was determined in a sequence of simulations on small square lattices of lateral size 21, 23, ... up to 101 [23]. As initial configuration on each of them a single mound was prepared. It persisted during deposition of 1000 monolayers, and the average evaporation rate was determined from a sequence of 25 runs. The data presented in Figure 1 show that  $\Delta v(\xi) > 0$  and  $\nu = 1.5 \pm 0.1$ , which is consistent with direct observations of coarsening on large lattices (cf. Fig. 1).

An analytical evaluation of  $\Delta v(\xi)$  is possible for the continuum equation, which will also allow us to derive the scaling of the crossover times (cf. Fig. 3) with  $\alpha$ . We recall the surface profile of Figure 4. The cones show two lateral lengthscales: (i) their size  $\xi$ , which for late times is much larger than (ii)  $\ell_D$ , the diameter of the tips and the valleys (=O(1) in our rescaled units) which is independent of  $\xi$ .

Thus for a mound on a d-dimensional surface the fraction of the surface covered by the tip is  $(1/\xi)^d$ . The surrounding trough has codimension one and a relative

weight  $1/\xi$ , while the major part of the surface consists of the sloped sides of the conical mounds.

Evaporation is less pronounced on the mounds' sides whereas it is enhanced by an amount of order  $\alpha^2$  on the horizontal parts, i.e. on the tip and in the surrounding valley. As a consequence equation (5) also holds for the continuum equation, where  $v_0$  is the evaporation rate on the mounds' sides, and the enhanced mass loss from small mounds is mainly due to the surrounding valley, i.e.  $\Delta v(\xi) \sim \alpha^2/\xi$ . So the timescale for mound coalescence is  $t_{\xi} \sim w/\Delta v(\xi) \sim \xi^2/\alpha^2$  (due to the stable slope,  $w \sim \xi$ ), and it follows that  $\xi \sim \alpha t^{1/2}$ . Incidentally, the same coarsening law was found in the one-dimensional case [18].

The initial increase  $\xi \sim t^{1/4}$  is not due to evaporation and thus the same for all values of  $\alpha$  (see Figure 3). Together with the late time behavior  $\xi \sim \alpha t^{1/2}$  this yields the estimate  $t_{\alpha} \sim \alpha^{-4} = (x_s/\ell_D)^4$  for the time at which evaporation begins to dominate the coarsening process. Rescaling time as  $t/t_{\alpha}$  and length as  $\xi/t_{\alpha}^{1/4}$ , and omitting the initial fast increase puts all curves and in particular the crossover times  $t_{\alpha}$  on top of each other, as shown in the inset of Figure 3.

We emphasize that fast coarsening for the continuum equation is due to the dominance of evaporation from valleys compared to the rest of the mounds. Direct inspection shows that in the KMC simulations more atoms in fact evaporate from the *upper* parts of the mounds. This explains why the coarsening exponent observed for the lattice model is smaller than 1/2: Given enhanced evaporation only on the tips,  $\Delta v(\xi)$  is of the order of  $\alpha^2/\xi^d$ , leading to  $\xi \sim (\alpha^2 t)^{1/(d+1)}$  in d dimensions, hence z=3 for d=2 as argued previously. To improve on this estimate, more detailed information about the shape of mounds and its coupling to the evaporation rate would be needed. It is nevertheless interesting to note that the coarsening exponent 1/z = 1/(d+1) is always larger than the value 1/z = 1/(d+2) obtained for noise-induced coarsening [21], indicating that our conclusions will not be modified by shot noise.

In summary, we have identified a general mechanism for fast mound coarsening in unstable growth with desorption. While the detailed appearance of the effect is different in the lattice model as compared to the continuum equation, in both cases the key feature is the dependence of growth rate on mound size. This gives us confidence that the phenomenon is robust and will be observed under suitable experimental conditions.
